

Many of the slides in this lecture are either from or adapted from slides provided by the authors of the textbook "Computer Systems: A Programmer's Perspective," 2nd Edition and are provided from the website of Carnegie-Mellon University, course 15-213, taught by Randy Bryant and David O'Hallaron in Fall 2010. These slides are indicated "Supplied by CMU" in the notes section of the slides.

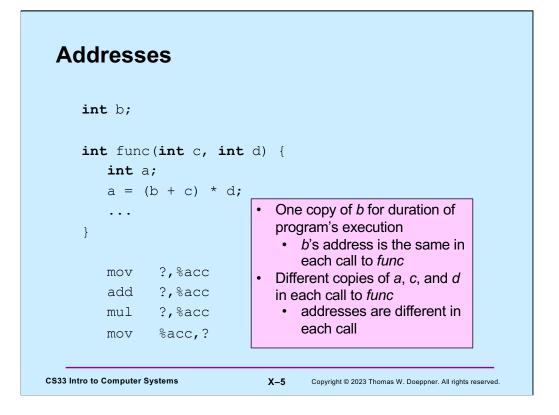

Jump instructions cause the processor to start executing instructions at some specified address. For conditional jump instructions, whether to jump or not is determined by the values of the condition codes. Fortunately, rather than having to specify explicitly those values, one may use mnemonics as shown in the slide.

We'll see examples of their use in an upcoming lecture, when we're looking at x86 assembler instructions.

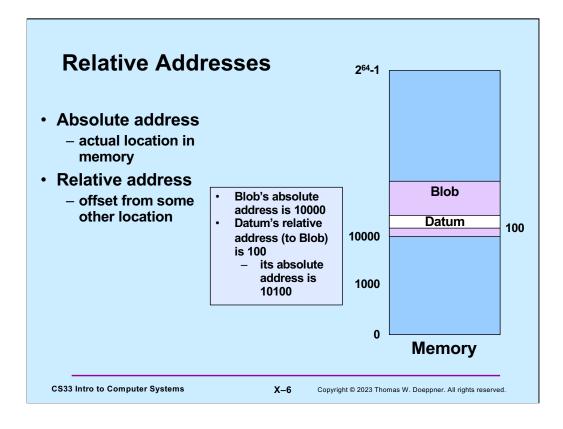

In the C code above, the assignment to a might be coded in assembler as shown in the box in the lower left. But this brings up the question, where are the values represented by **a**, **b**, **c**, and **d**? Variable names are part of the C language, not assembler. Let's assume that these global variables are located at addresses 1000, 1004, 1008, and 1012, as shown on the right. Thus, correct assembler language would be as in the middle box, which deals with addresses, not variable names. Note that "mov 1004,%acc" means to copy the contents of location 1004 to the accumulator register; it does not mean to copy the integer 1004 into the register!

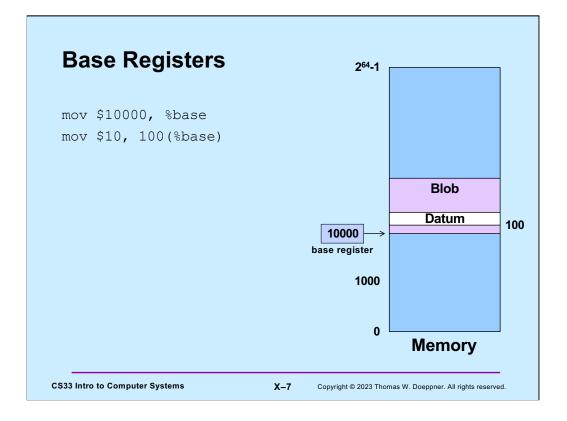

Beginning with this slide, whenever we draw pictures of memory, lower memory addresses are at the bottom, higher addresses are at the top. This is the opposite of how we've been drawing pictures of memory in previous slides.

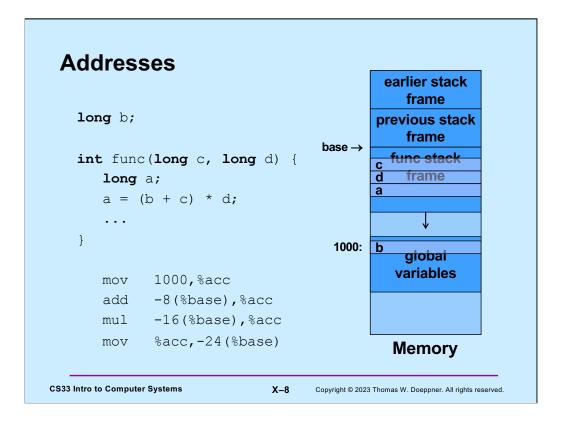

Here we rearrange things a bit. **b** is a global variable, but a is a local variable within **func**, and **c** and **d** are arguments. The issue here is that the locations associated with **a**, **c**, and **d** will, in general, be different for each call to **func**. Thus, we somehow must modify the assembler code to take this into account.

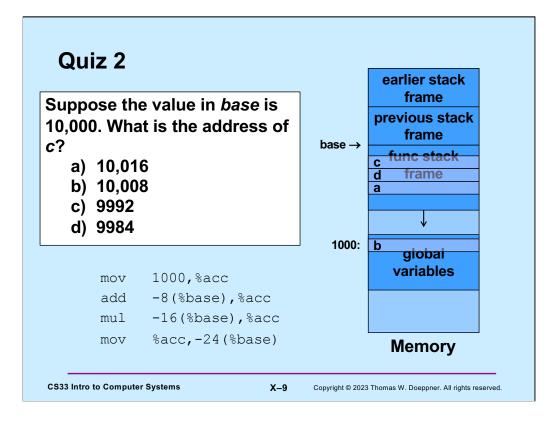

Note that both positive and negative offsets might be used.

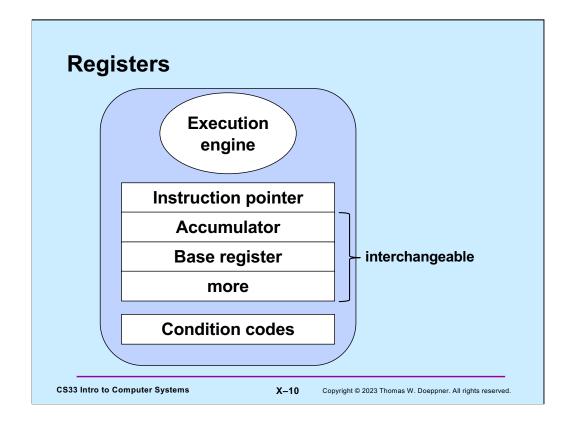

Here we load the value 10,000 into the base register (recall that the "\$" means what follows is a literal value; a "%" sign means that what follows is the name of a register), then store the value 10 into the memory location 10100 (the contents of the base register plus 100): the notation \mathbf{n} (%base) means the address obtained by adding \mathbf{n} to the contents of the base register.

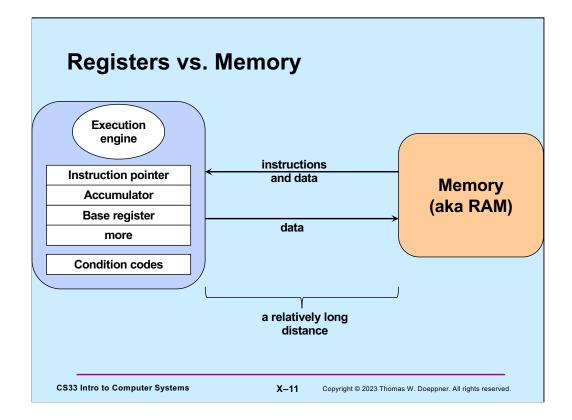

Here we return to our earlier example. We assume that, as part of the call to **func**, the base register is loaded with the address of the beginning of **func**'s current stack frame, and that the local variable **a** and the parameters **c** and **d** are located within the frame. Thus, we refer to them by their offset from the beginning of the stack frame, which are assumed to be **-24**, **-8**, and **-16**. Since the stack grows from higher addresses to lower addresses, these offsets are negative. Note that the first assembler instruction copies the contents of location 1000 into **%acc**.

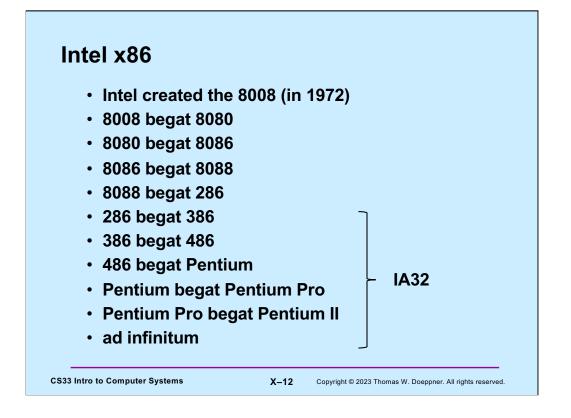

We've now seen four registers: the instruction pointer, the accumulator, the base register, and the condition codes. The accumulator is used to hold intermediate results for arithmetic; the base register is used to hold addresses for relative addressing. There's no particular reason why the accumulator can't be used as the base register and vice versa: thus, they may be used interchangeably. Furthermore, it is useful to have more than two such dual-purpose registers. As we will see, the x86 architecture has eight such registers; the x86-64 architecture has 16.

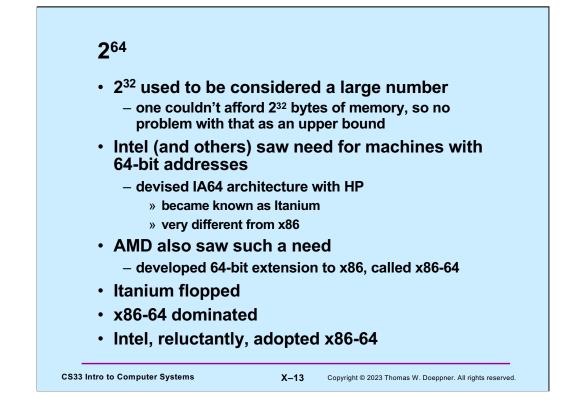

Why do we make the distinction between registers and memory? Registers are in the processor itself and can be read from and written to very quickly. Memory is on separate hardware and takes much more time to access than registers do. Thus, operations involving only registers can be executed very quickly, while significantly more time is required to access memory. Processors typically have relatively few registers (the IA-32 architecture has eight, the x86-64 architecture has 16; some other architectures have many more, perhaps as many as 256); memory is measured in gigabytes.

Note that memory access-time is mitigated by the use of in-processor caches, something that we will discuss in a few weeks.

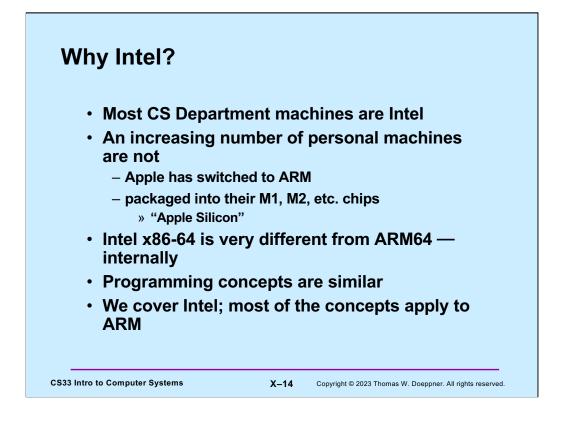

The early computers of the x86 family had 16-bit words; starting with the 386, they supported 32-bit words.

 2^{32} = 4 gigabytes.

 2^{64} = 16 exbibytes.

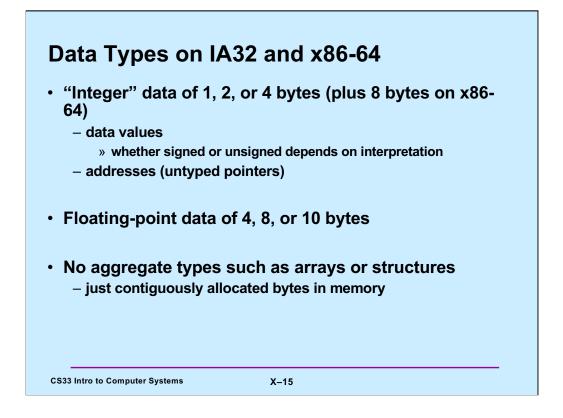

All SunLab computers are x86-64.

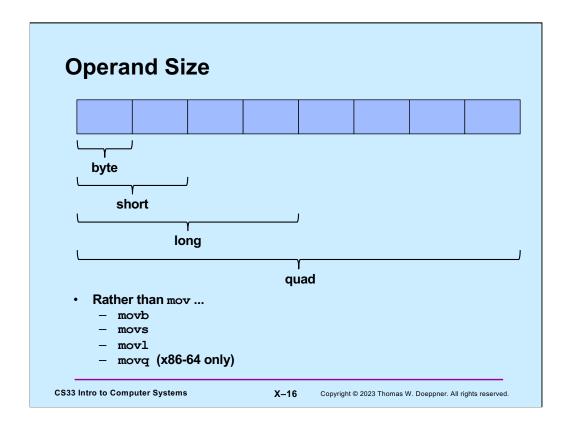

ARM originally stood for Acorn RISC machine. Acorn was a British computer company that was established in 1978, but no longer exists. RISC stands for Reduced Instruction Set Computer. The RISC concept was devised in the 1980s and was very popular in the 80s and 90s. The idea is to design computers with relatively few instructions, but implement those instructions so they can execute very quickly. The fastest computers in the 80s and 90s were RISC computers. But Intel, who built computer chips with fairly complex instruction sets (CISC), learned how to make their computers run really fast as well. That, coupled with the fact that Windows ran exclusively on Intel, helped Intel stay in the lead.

ARM later became Advanced RISC Machine. Now, it doesn't stand for anything, It's just ARM.

Apple (whose computers originally ran Motorola 68000 processors before they switched to Intel) decided that they could make more cost-effective and faster processors by adapting the ARM design and including GPUs (graphics processing units). GPUs are specialized processors that help with image processing, but also can be used with other computations that have a lot of inherent parallelism. Apple refers to their new chips as M1 and M2 (presumably an M3 is not far behind).

Most instructions come in three (on IA32) or four (on x86-64) forms, one for each possible operand size.

Note the confusion: long on x86 is 32 bits, but long in C is 64 bits.

Note that some assemblers (in particular, those of Microsoft and Intel) use a different syntax. Rather than tag the mnemonic for the instruction with the operand size, they tag the operands.

Note that %ebp/%rbp may be used as a base register as on IA32, but they don't have to be used that way. This will become clearer when we explore how the runtime stack is accessed. The convention on Linux is for the first 6 arguments of a function to be in registers %rdi, %rsi, %rdx, %rcx, %r8, and %r9. The return value of a function is put in %rax.

Note also that each register, in addition to having a 32-bit version, also has an 8-bit (one-byte) version. For the numbered registers, it's, for example, %r10b. For the other registers it's the same as for IA32.

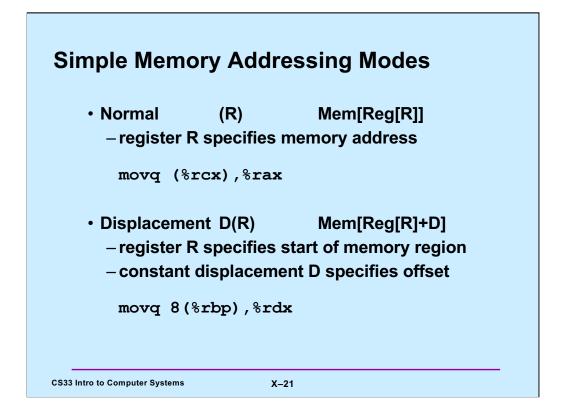

Based on a slide supplied by CMU.

Some assemblers (in particular, those of Intel and Microsoft) place the operands in the opposite order. Thus, the example of the slide would be "addl %rax,8(%rbp)". The order we use is that used by gcc, known as the "AT&T syntax" because it was used in the original Unix assemblers, written at Bell Labs, then part of AT&T.

If one thinks of there being an array of registers, then "Reg[R]" selects register "R" from this array.

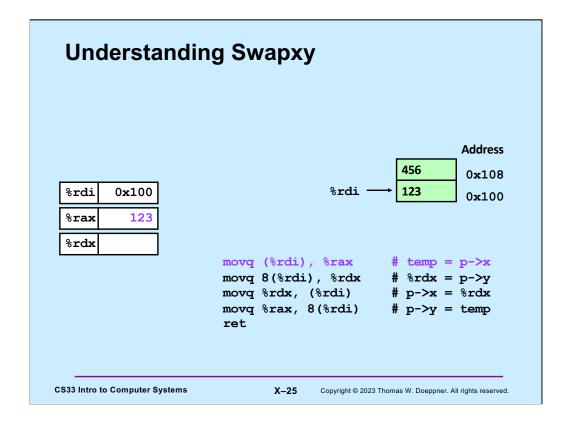

Here we have a simple function that swaps the two components of a structure that's passed to it. (Assume that %rdi contains the argument.)

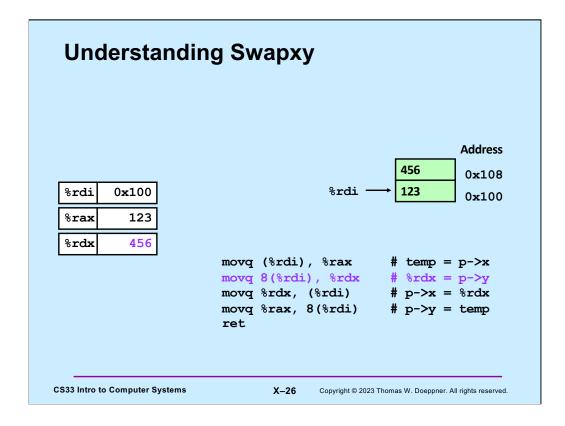

In addition to using %rdi to contain the argument (the address of the structure), we use %rax to contain the value of **temp** and %rdx to effectively be another temporary that holds the value of p->y.

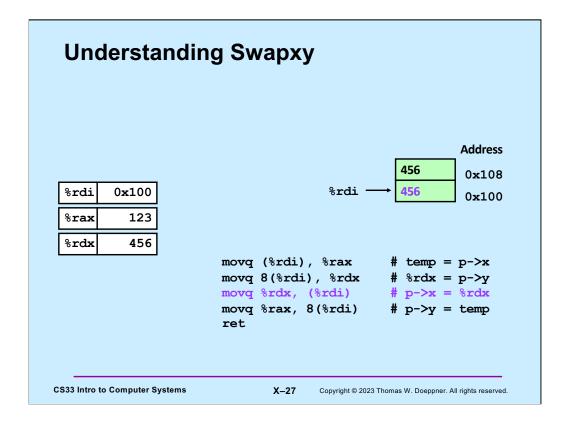

When we enter **swapxy**, %rdi contains the address of the structure.

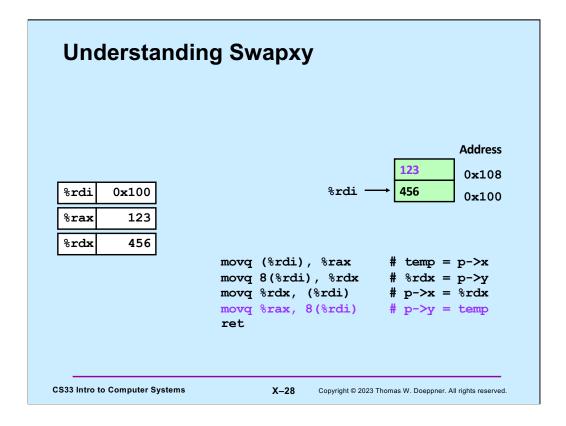

We copy the first component of p into **temp**, which is held in %rax.

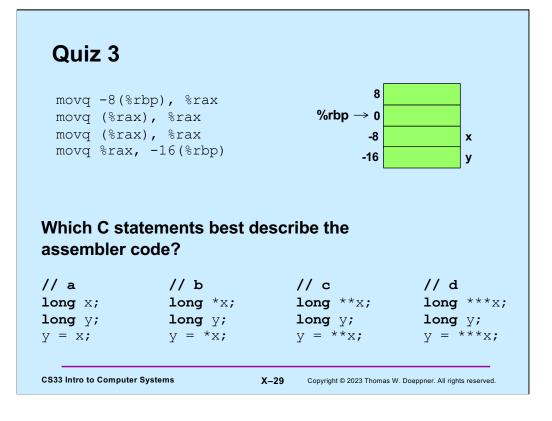

We then copy the second component into %rdx.

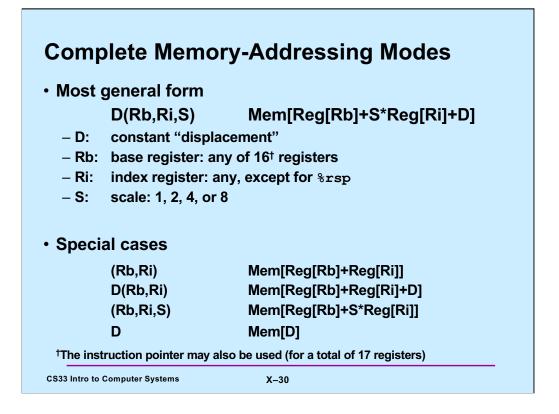

The second component, which we'd copied into %rdx, is now copied into the first component of the structure itself.

Finally, we update the second component, copying into it what had been the first component.

The instruction pointer is referred to as %rip. We'll see its use (in addressing) a bit later in the course.

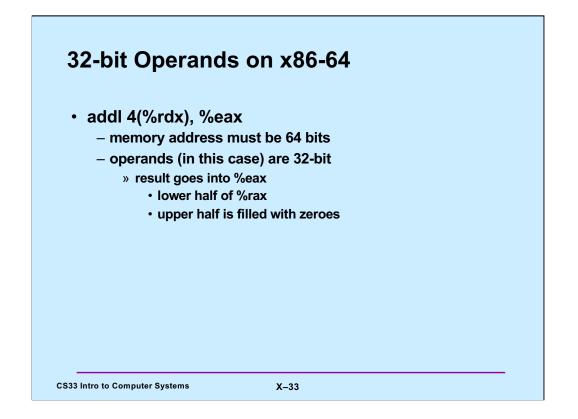

%rdx	0xf000		
%rcx	0x0100	-	
Expression		Address Computation	Address
0x8(%r	rdx)	0xf000 + 0x8	0xf008
0x8(%r (%rdx,	•	0xf000 + 0x8 0xf000 + 0x100	0xf008 0xf100
(%rdx,	•

Note that a function returns a value by putting it in %rax.

On x86-64, for instructions with 32-bit (long) operands that produce 32-bit results going into a register, the register must be a 32-bit register; the higher-order 32 bits are filled with zeroes.

Quiz 4		
	1009:	0x09
What value ends up in %ec	1008:	0x08
	1007:	0x07
A1000	1006:	0x06
movq \$1000,%rax	1005:	0x05
movq \$1,%rbx	1004:	0x04
<pre>movl 2(%rax,%rbx,2),%ecx</pre>	1003:	0x03
a) 0x04050607	1002:	0x02
b) 0x07060504	1001:	0x01
c) 0x06070809	%rax \rightarrow 1000:	0x00
d) 0x09080706
